ABSTRACT

Endosulfan is an organochlorine insecticide and acaricide used to control a broad range of insect and arthropod pests on a wide variety of crops in many agrosystems. It can cause acute and chronic toxicity. Endosulfan is a neurotoxin, haematoxin, genotoxin and nephrotoxin. Toxicity of this insecticide on reproductive organs is confirmed. So this article reviews experimental and epidemiological studies of reproductive toxicity of endosulfan in males. The Literature search was carried on PubMed for the years 1994 -2014. Twelve experimental studies and two human studies on Male Reproductive Toxicity induced by endosulfan were identified. Based on the findings, it suggest that endosulfan can affect the male reproductive system and also that these effects are likely to be larger if exposure occurs during the developmental phase. Further investigation of endosulfan as reproductive toxicant is warranted.

Keywords: Endosulfan, Organochlorine insecticide, Male reproductive system

INTRODUCTION

Chemicals released into the environment may have either overt toxic effects or more subtle effects that influence long-term survival and reproduction. Numerous occupational hazards to male reproductive function are known but exposure prevalence is hardly sufficient to play a role for reduced sperm count in the general male population1-4. Endosulfan is a chlorinated hydrocarbon insecticide of the cyclodiene subgroup, which acts as a poison to a variety of insects. It is used on a wide variety of crops including tea, coffee, cotton, fruits and vegetables, as well as on rice, cereals, maize, or other grains. It has been classified as a moderately hazardous (class II) pesticide [World Health Organization (WHO) 2002]. Neurotoxicity is the major end point of concern in acute endosulfan exposure in human beings and experimental animals. The subacute and chronic toxicity studies of endosulfan suggest that the liver, kidneys, immune system, and testes are the main target organs1. Endosulfan is banned in more than 75 countries and in some countries like Argentina, Peru and Chile, the demand for alternative pesticide substances increased after the ban. Recently, India witnessed a furore over banning endosulfan, with reports appearing on endosulfan poisoning, and the subsequent political pressure. Moreover, Endosulfan was previously banned in Kerala and has been recently banned in Bihar5.

Endosulfan not only acts as a hormone disruptor, but it also affects neurotransmitter systems of many species such as rats, catfish, and bullfrog tadpoles. For example, endosulfan suppressed testosterone and 17ß-estradiol concentrations in neonatal rats and also increased thyroxine (T4) levels in catfish, and induced neurotoxic effects including increased excitability, trembling, and deficits in operant learning performance via the disruption of cholinergic, dopaminergic, and serotonergic neurotransmitter systems in freshwater fishes, pigeons and rats1. Oral LD50 (lethal dose sufficient to kill 50% of population) endosulfan in rats is 80 mg/kg. With reference to impact of endosulfan on reproductive system, there is no review summarizing the studies related to occupational or experimental exposure of endosulfan on male reproductive functions. So this present paper was aimed to critically review experimental and epidemiological studies of reproductive toxicity of endosulfan in males to summarize current knowledge and to suggest possible further research in this field.

For Search criteria

The Literature search was carried on most recent medical data base (PubMed with MeSH )for the years 1994 - 2014 with the following key words like: endosulfan: toxicity: male: reproduction: epidemiological studies: animal studies: human. Besides the data base search, the reference lists of the selected articles were screened for other articles that could be useful. After collecting the abstracts, these references were searched manually for relevant papers in the English language literature. 12 experimental studies on Male Reproductive Toxicity induced by endosulfan were identified. But there were only two evident studies on humans.

For the human data, practically we had the idea to select the articles concerning spermatozoal, histopathological, and hormonal aspects, and birth rates in workers exposed to pesticides. But we found only one human study of endosulfan on male reproductive functions which did not fully met our selection criteria.
Experimental data of Endosulfan on Male reproductive function

In recent years, there has been growing concern about toxicity of a number of chemicals, including pesticides, on the male reproductive system. The effects of endosulfan on the Male reproductive system in experimental animals have been variable, depending on age at exposure, dose, duration of exposure, and study end points. Table 1 summarizes the animal (rat and mice) studies of endosulfan on male reproductive functions. Routine gross and histopathologic examination of the reproductive organs of male rats that consumed doses of 2.6 and 18 ppm/day for 2 years revealed no toxic effects. Later on, more detailed studies in adult rats exposed to 2.5, 5, and 18 ppm/day for 5 days per week for 10 weeks showed reduced intratesticular sperm headcounts, sperm abnormalities, and changes in the marker enzymes of testicular activities, such as lactate dehydrogenase, sorbitol dehydrogenase, g-glutamyl transpeptidase and glucose-6-phosphate dehydrogenase, providing further evidence of effects on spermatogenesis.

Exposure of younger animals (3 weeks old) showed marked depletion of sperm count as well as decreased daily sperm production at a dose of 2.5 mg/kg/day, which was earlier seen at the same dose in adult rats by the same investigators. More studies have shown that exposure of pregnant rats to endosulfan at 1 mg/kg/day from day 12 through parturition leads to decreased spermatogenesis in offspring. Dalson et al. (1999) reported similar observations at 3 mg/kg/day but not at 1.5 mg/kg/day and they attributed this to strain variation.

There are reports of testicular toxicity of endosulfan manifested as decreased spermatogenesis and testicular hormone synthesis (steroidogenesis), as evidenced by a decrease in spermatid count in testes and in sperm count in the cauda epididymis and by changes in marker enzymes for testicular steroidogenesis in a dose of 1.0 mg/kg body weight for 30 days in pubertal rats. These effects were seen at much lower dosages and shorter durations if exposures occurred during the prenatal or prepubertal periods.

Rao M et al (2005) studied the effect of endosulfan on postnatal exposure of testis in the rat. Endosulfan significantly affected the testicular function enhancing the incidence of abnormal spermatozoa, decreasing the sperm count and sperm motility in a dose dependent manner. This study also showed that L-ascorbic acid prevents the adverse effects considerably in the rat.

Yet in a recent study, Endosulfan (2 µg/ml) had no significant effect on progeny production and on the expression of certain genes associated with reproduction. However, exposed males performed worse in sperm competition, both as 1(st) and 2(nd) male competitors. Wang N et al. in year 2014 showed that testosterone propionate (TP) significantly prevented the declines of concentration and motility rates in sperm, reduced the rate of sperm abnormalities in epididymis; and antagonized the decreases in spermatozoa cell and sperm numbers in testes induced by endosulfan (0.8 mg/kg/day endosulfan).

Epidemiological studies of Endosulfan on Male reproductive system

The results of the human study also showed a significant decrease sexual maturity rating (SMR) scores and serum testosterone levels and higher levels of serum LH in study group (Exposed school children aged between 5-19 years), the observations of low testosterone levels in male children conform with the animal studies. Lower SMR scores appear to reflect lower serum testosterone levels for age. In their study, they were not able to confirm disturbed spermatogenesis observed in animal studies.

In a cross-sectional study on humans an inverse associations between Organochlorine (OC) pesticide concentrations (endosulfan) and testosterone in men was observed which suggests that these OC compounds may have triggered anti-androgenic effects in men and estrogenic effects in women in this population.

Mechanism of Action

The question of the biological mechanisms of endosulfan damage has also to be clarified. It is also difficult to say if the deposition of endosulfan in the tubules of the testis is important or not if it is the localisation or distribution of endosulfan in spermatozoa that determines the possible adverse effect. A theory about the blood-testis barrier suggests that the germinal epithelium is divided into two compartments: the basal compartment, related to spermatogenesis, and the adluminal compartment, mainly related to the more differentiated cells. The different substances (nutritional or toxic) reach the first compartment more easily and seem to be excluded from the second by occlusive junctions, located in the lateral surfaces of Sertoli cells and immediately above the spermatogonia layer. Therefore, the interaction between endosulfan and germinal cells is easier for spermatogonia than for differentiated cells. This could lead to damage of spermatogonia.

Another mechanism shown by Wang N (2012) et al. includes that endosulfan could directly damage sperm structures by oxidative stress, leading to a decrease in sperm quantity and quality. It also could indirectly cause a decline in reproductive function by damaging the structure of spermatogonia.
mitochondria, resulting in energy metabolism dysfunction, which could be one of the mechanisms behind the reproductive toxicity induced by endosulfan\(^2\). Furthermore, this mechanism exposure induces the apoptosis of spermatogenic cells via mitochondria-dependent pathway mediated by oxidative stress resulting in the damage of mitochondrial structure and mitochondrial dysfunction\(^25\).

**Future Research**

As there are less studies reported on humans, future studies on human male reproductive effects of endosulfan should consider by using several methodological issues—such as the standardisation of analytical procedures with strict quality controls within and between laboratories—the adoption well defined terms of the outcome to be measured, the use of concurrent control subjects, the analysis of semen with respect to the time variables, the adoption of standardized criteria for information and motivation of the participants, and exposure assessment. It is also important to study large cohorts to evaluate possible effects at the endosulfan concentrations currently encountered in occupationally exposed populations and to design such studies to characterise the dose-response relation and evaluate change of values over time. This will also enable establishment of a no effect level and proper biological limit values. The question of the indicator of exposure should also be clarified, taking into account that possible indicators—such as seminal endosulfan—may be more useful in fertility studies than the indicators of recent exposure. It should be underlined that interactions with other occupational and non-occupational exposures must be considered and every possible confounding factor should be controlled for. In this respect, integrated studies should be promoted which will evaluate not only seminal and endocrine end points, but also other aspects such as the time to pregnancy.

**CONCLUSION**

Endosulfan was classified by the WHO in the category of technical products that are moderately hazardous. It has been shown that endosulfan has estrogenic property and male rats are more sensitive to the chronic effect of endosulfan than female rats. From these studies it suggest that endosulfan can affect the male reproductive system and also that these effects are likely to be greater if exposure occurs during the developmental phase. These findings warrant further investigation and reinforce the need to minimize exposure to pesticides in occupational settings.
